STIM1 (stromal interacting molecule 1), an endoplasmic reticulum (ER) protein that controls store-operated Ca$^{2+}$ entry (SOCE), redistributes into punctate at the cell periphery after store depletion. This redistribution is suggested to have a causal role in activation of SOCE. However, whether peripheral STIM1 punctate that are involved in regulation of SOCE are determined by depletion of peripheral or more internal ER has not yet been demonstrated. Here we show that Ca$^{2+}$ depletion in subplasma membrane ER is sufficient for peripheral redistribution of STIM1 and activation of SOCE. 1 \textmu M thapsigargin (Tg) induced substantial depletion of intracellular Ca$^{2+}$ stores and rapidly activated SOCE. In comparison, 1 nM Tg induced slower, about 60–70% less Ca$^{2+}$ depletion but similar SOCE. SOCE was confirmed by measuring \textit{I}_{\text{SOC}} in addition to Ca$^{2+}$, Mn$^{2+}$, and Ba$^{2+}$ entry. Importantly, 1 nM Tg caused redistribution of STIM1 only in the ER-plasma membrane junction, whereas 1 \textmu M Tg caused a relatively global relocalization of STIM1 in the cell. During the time taken for STIM1 relocalization and SOCE activation, 1 nM Bodipy-fluorescein Tg primarily labeled the subplasma membrane region, whereas 1 \textmu M Tg labeled the entire cell. The localization of Tg in the subplasma membrane region was associated with depletion of ER in this region and activation of SOCE. Together, these data suggest that peripheral STIM1 relocalization that is causal in regulation of SOCE is determined by the status of [Ca$^{2+}$] in the ER in close proximity to the plasma membrane. Thus, the mechanism involved in regulation of SOCE is contained within the ER-plasma membrane junctional region.

Store-operated calcium entry (SOCE)\textsuperscript{2} is activated in response to depletion of Ca$^{2+}$ in intracellular Ca$^{2+}$ store(s).

membrane (probably interacting with SOCE channels), this ER Ca\(^{2+}\) store would have to be depleted for activation of SOCE. Further, these stores would have to remain in a depleted state in order to retain the punctate localization of STIM1, which is required to maintain SOCE in an activated state. However, conditions typically used for activating SOCE and assessing STIM1 function (8–13) involve high concentrations of thapsigargin (Tg) or agonists that induce substantial and global depletion of internal Ca\(^{2+}\) stores. Thus, it is unclear whether changes in the local Ca\(^{2+}\) store (i.e. in the vicinity where regulation of SOCE seems to be taking place) regulate relocation of STIM1 and activation of SOCE or whether signals from more interior regions of the cell are required.

In this study, we have assessed whether STIM1 regulation of SOCE is dependent on the [Ca\(^{2+}\)] in subplasma membrane ER or in more internal ER. We have used low concentrations of Tg to slow down the process of ER depletion and activation of SOCE. It has been previously shown that low concentrations of Tg that induce only partial depletion of internal Ca\(^{2+}\) stores result in a slow but almost complete activation of \(I_{\text{CRAC}}\) (14, 15), although these previous studies do not clarify the location of the SOCE-coupled ER Ca\(^{2+}\) store. We demonstrate that as Tg diffuses into the periphery of the cell, Ca\(^{2+}\) stores in this region are depleted, and this is associated with activation of SOCE. SOCE is not further enhanced by depletion of more internal ER. Further, we show that mobilization of the SOCE regulatory protein STIM1 in the subplasma membrane region of the cells is associated with depletion of ER in this region. Together, our data suggest that STIM1 senses [Ca\(^{2+}\)] within ER localized in the ER-plasma membrane junctional regions and that the status of this peripheral ER Ca\(^{2+}\) store determines peripheral relocation of STIM1 that is required for activation of SOCE.

**Experimental Procedures**

**Materials**—Bodipy-fluorescent thapsigargin (BD-Tg), Fura-2/AM, Mag-Fluo4AM, Fluo-4AM, and the ER-Tracker Red dye and Vybrant staining assay were obtained from Invitrogen. Tg was obtained from Calbiochem. Carbachol (CCh) and 2-aminoethyl diphenyl borinate (2-APB) were obtained from Sigma. Glass-bottomed 35-mm Petri dishes were obtained from MatTek Corp. (Ashland, MA). Glass coverslips were obtained from Fisher. The rabbit antibody against phosphorylated PERK (phospho-PERK) was obtained from Cell Signaling Technology (Danvers, MA). The mouse anti-STIM1 antibody was obtained from BD Biosciences, whereas the fluorescein isothiocyanate-conjugated donkey anti-mouse antibody was from Jackson Immunoresearch (West Grove, PA). The cDNA for untagged STIM1 was obtained from OriGene (Rockville, MD).

**Cell Culture and Transient Transfection**—HSG cells were cultured on glass coverslips and were transiently transfected with untagged STIM1 (1 µg) or YFP-STIM1 (1 µg) for 48 h using the method described previously (16). For [Ca\(^{2+}\)] measurements and live cell imaging experiments, cells were plated on glass-bottomed 35-mm Petri dishes. For patch clamp measurement and TIRF, cells were plated on glass coverslips.

**[Ca\(^{2+}\)]\(_{\text{ER}}\) Measurements**—Measurements with 3 µM Mag-Fluo4AM and analyses of data were conducted as described previously (17, 18).

**Electrophysiological Measurements**—Whole cell-attached patch clamp measurements were performed as described previously (1, 17–19). For Ca\(^{2+}\) current measurements, the external solution was composed as follows: 145 mM NaCl, 5 mM CsCl, 1 mM MgCl\(_2\), 10 mM CaCl\(_2\), 10 mM HEPES, 10 mM glucose, pH 7.4 (NaOH). For DVF-Na\(^{+}\) current measurements, the external solution was composed as follows: 165 mM NaCl, 5 mM CsCl, 10 mM EDTA, 10 mM HEPES, 10 mM glucose, pH 7.4 (NaOH). The patch pipette contained the standard intracellular solution, which was composed as follows: 145 mM cesium methane sulfonate, 8 mM NaCl, 5 mM MgCl\(_2\), 10 mM HEPES, 10 mM EGTA, pH 7.2 (CsOH).

**Immunodetection of Phosphorylated PERK**—Lysates from HSG cells were prepared, and immunoblotting using phospho-PERK antibody was carried out as described previously (20, 21).

**Immunofluorescence and Confocal Microscopy**—Immunofluorescence was conducted in a similar manner as described previously (22). Cells were stained with the mouse anti-STIM1 antibody (1:100 dilution) and probed using a donkey anti-mouse antibody conjugated to fluorescein isothiocyanate (1:100 dilution). Fluorescence images were acquired using a confocal laser-scanning microscope Leica TCS-SP2 attached to an upright Leica DM-RE7 microscope as described earlier (22).

**Live Cell Imaging Using BD-Tg**—HSG cells were scanned using Leica TCS SP2 attached to an inverted Leica DM-IRE2 microscope. BD-Tg was added to the cells at 1 µM and 1 nM concentrations. Fluorescence intensity in selected regions of the cell was measured. Images were acquired every 3 s for 3 min. Background fluorescence was subtracted from each data point.

**[Ca\(^{2+}\)]\(_{\text{ER}}\) Measurements**—HSG cells were loaded with 3 µM Mag-Fluo4AM in a Ca\(^{2+}\)-containing standard extracellular solution (Ca\(^{2+}\)-SES) for 1 h at 37 °C in 5% CO\(_2\). The Ca\(^{2+}\)-SES was composed as follows: 145 mM NaCl, 5 mM CsCl, 1 mM MgCl\(_2\), 1 mM CaCl\(_2\), 10 mM HEPES, 10 mM glucose, pH 7.4 (NaOH) (23). After incubation, cells were then rinsed with Ca\(^{2+}\)-free SES and used in live cell imaging experiments on a Leica DM-IRE2 microscope as described above or in TIRF imaging as described below.

**Vybrant Staining Assay**—Vybrant staining assay was used to evaluate apoptosis, using the method described previously (24).

**TIRF Imaging**—HSG cells were seeded and cultured overnight on glass coverslips, which formed the base of a perfusion chamber that was mounted on the stage of an Olympus IX81 motorized inverted microscope (OPELCO, Dulles, VA). Prior to the start of imaging, cells were loaded with 4 µM Fluo-4AM in a Ca\(^{2+}\)-SES for 1 h at 37 °C in 5% CO\(_2\). To determine ER localization in the subplasma membrane regions, cells were loaded with 1 µM ER-Tracker Red dye for 1 h at 37 °C. TIRF imaging was then conducted as described previously (25). Changes in Fluo-4 fluorescence were calculated using KaleidaGraph software (Red Rock Software, Salt Lake City, UT) and were expressed as ΔF/F\(_0\), where F is the fluorescence captured at a particular time point and F\(_0\) is the mean fluorescence intensity from the initial 20 captured images.
Regulation of SOCE

RESULTS

Submaximal Depletion of ER Ca\(^{2+}\) Store Activates SOCE—Stimulation of HSG cells by the endoplasmic Ca\(^{2+}\) pump inhibitor Tg (1 \(\mu M\)) induces an initial rapid increase in [Ca\(^{2+}\)]\(_{i}\) (represented by the 340/380 fluorescence ratio; Fig. 1A) due to internal Ca\(^{2+}\) release, which is detected as a transient [Ca\(^{2+}\)]\(_{i}\) increase in the absence of external Ca\(^{2+}\). The addition of Ca\(^{2+}\) to the external medium after internal store depletion induces a second increase in [Ca\(^{2+}\)]\(_{i}\), due to Ca\(^{2+}\) influx. At this concentration, Tg induces almost complete depletion of the internal IP\(_3\)-sensitive Ca\(^{2+}\) store (the addition of Tg after carbachol induced some additional Ca\(^{2+}\) release but not vice versa; data not shown). Further, caffeine does not affect Tg- or carbachol-induced [Ca\(^{2+}\)]\(_{i}\) increase in HSG cells (data not shown). The contribution of mitochondrial Ca\(^{2+}\) transport to the Tg-stimulated [Ca\(^{2+}\)]\(_{i}\) changes was not assessed.

To determine the extent of [Ca\(^{2+}\)]\(_{ER}\) depletion required for activation of SOCE, we examined internal Ca\(^{2+}\) release and Ca\(^{2+}\) entry induced by lower [Tg]. 0.5 \(\mu M\), 10 \(\mu M\), and 1 \(\mu M\) Tg induced slower and less internal Ca\(^{2+}\) release than 1 \(\mu M\) Tg (Fig. 1B). Importantly, substantial Ca\(^{2+}\) entry was seen at the lower [Tg], and neither the rates nor amplitudes of the [Ca\(^{2+}\)]\(_{i}\) increase at the various [Tg] were significantly different from each other (see Fig. 1D and also traces in Fig. 1, E and G). The extent of store depletion was assessed by the addition of 1 \(\mu M\) Tg after treatment of cells with lower [Tg] (Fig. 1, C and D). The 1 \(\mu M\) Tg-induced [Ca\(^{2+}\)]\(_{i}\) increase was reduced by <50% in cells pretreated with 1 \(\mu M\) Tg for 500 s, suggesting that at least 50% of internal Ca\(^{2+}\) store was not associated with activation of Ca\(^{2+}\) entry. Similarly, 10 \(\mu M\) and 0.5 \(\mu M\) also induced less store depletion compared with 1 \(\mu M\) Tg (see Fig. 1D). These data demonstrate that Ca\(^{2+}\) entry is activated even when internal Ca\(^{2+}\) stores are incompletely depleted. To confirm that SOCE is activated by 1 \(\mu M\) Tg, we examined the effects of Gd\(^{3+}\) and 2-APB, both of which are used to block SOCE (26, 27). Ca\(^{2+}\) entry stimulated by 1 \(\mu M\) and 1 \(\mu M\) Tg was inhibited by 1 \(\mu M\) Gd\(^{3+}\) and 10 \(\mu M\) 2-APB (Fig. 1, E–H, respectively). The inhibitory effect of 1 \(\mu M\) Gd\(^{3+}\) was seen whether it was added before or after 1 \(\mu M\) CaCl\(_2\) (Fig. 1E, inset; data with 1 \(\mu M\) Tg not shown). These findings strongly suggest that SOCE is activated under conditions where there is relatively less depletion of the ER Ca\(^{2+}\) store.

1 \(\mu M\) Tg, like 1 \(\mu M\) Tg, also activated the previously described inwardly rectifying store-operated Ca\(^{2+}\) current, \(I_{SOCE}\), in HSG cells (1) (Fig. 2, A–C). However, the magnitude of the current with 1 \(\mu M\) Tg was about 60% less than that with 1 \(\mu M\) Tg, and there was also a longer lag before an increase in current was detected (209 ± 55 s compared with 20 ± 4 s with 1 \(\mu M\) Tg). Notably, the current developed rapidly after this lag period and appeared to be quite stable, unlike the current with 1 \(\mu M\) Tg, which inactivated more rapidly. These data are inconsistent with the Fura-2 data, which demonstrate that 1 \(\mu M\) and 1 \(\mu M\) Tg

---

**FIGURE 1. Activation of SOCE by incomplete depletion of ER Ca\(^{2+}\) stores.** A and B, Tg-induced intracellular Ca\(^{2+}\) release and Ca\(^{2+}\) entry in HSG cells. The various [Tg] used for activation of SOCE are indicated in the figure. C, Ca\(^{2+}\) release induced by 1 \(\mu M\) Tg in control cells (blue trace) and in cells previously treated with 1 \(\mu M\) Tg (black trace), indicating the extent of depletion of ER by 1 \(\mu M\) Tg. D, dose-response curve showing the effect of [Tg] on Ca\(^{2+}\) release (units; squares) and the rate of Ca\(^{2+}\) influx (units/s; circles). Data were plotted as mean ± S.E. from three or four separate experiments and expressed in 340/380 fluorescence ratio units; error bars were within the size of the symbols. Ca\(^{2+}\) influxes induced by 1 \(\mu M\) Tg and 1 \(\mu M\) Tg were blocked by 1 \(\mu M\) GdCl\(_3\) (E and G, respectively) and 10 \(\mu M\) 2-APB (F and H, respectively). A trace showing the inhibition of Ca\(^{2+}\) influx induced by 1 \(\mu M\) Tg by 1 \(\mu M\) GdCl\(_3\) added before 1 \(\mu M\) CaCl\(_2\) is shown as an inset (similar results were seen with 1 \(\mu M\) Tg; data not shown) in E. [Ca\(^{2+}\)]\(_{i}\) was measured in Fura-2-loaded cells and is expressed as 340/380 ratio. Each analog plot showing Ca\(^{2+}\) release and Ca\(^{2+}\) entry is representative of at least four experiments, each trace showing the average from at least 50 cells.
Regulation of SOCE

activate similar magnitude of SOCE, although activation is slower at the lower [Tg]. We hypothesized that this discrepancy could be due to a contribution of Ca\(^{2+}\)-induced Ca\(^{2+}\) release to the Fura-2 fluorescence measurements (28). Alternatively, it could be a result of recycling of Ca\(^{2+}\) into the ER store by residual SERCA activity in cells treated with the lower [Tg]. It should be noted that since \(I_{SOC}\) measurements were done in the presence of 10 mM external Ca\(^{2+}\), it is possible, despite the buffering of Ca\(^{2+}\) in the pipette solution, that Ca\(^{2+}\) entering the cell is taken back into the ER to partially refill the store (3). However, removal of external Ca\(^{2+}\) (as was the case in the Fura-2 assay) would allow this store to be substantially depleted. Uptake of Ca\(^{2+}\) into the ER by the residual SERCA activity in cells stimulated with low [Tg] will also result in lower ambient [Ca\(^{2+}\)]\(_i\), which would attenuate Ca\(^{2+}\)-dependent inactivation of SOCE and account for the relatively stable \(I_{SOC}\) in these cells.

To determine the possible contribution of Ca\(^{2+}\)-induced Ca\(^{2+}\) release to the Ca\(^{2+}\) entry into these cells, we used TIRFM to examine localization of heterologously expressed YFP-STIM1 in HSG cells.

Note that longer incubation with either the low or high Tg did not induce any further increase in SOCE. The addition of 1 mM Tg after stimulation with 1 \(nM\) Tg for 150 s demonstrated that there was about 30\% depletion of the internal Ca\(^{2+}\) store (data not shown, but compare with Fig. 1C). Together, these data demonstrate that SOCE is maximally activated by 150 s after 1 \(nM\) Tg treatment. To confirm this, SOCE was measured using Mn\(^{2+}\) as a Ca\(^{2+}\) surrogate (29). 50 s after the addition of 1 \(nM\) Tg, the rate of Fura-2 quenching was substantially less than that induced by 1 \(uM\) Tg (Fig. 3F). However, similar Mn\(^{2+}\) entry was seen in cells stimulated for 150 and 250 s with either 1 \(nM\) or 1 \(uM\) Tg (Fig. 3, G and H). In aggregate, these data suggest that depletion of SOCE-coupled stores with 1 \(nM\) Tg is slow at first due to recycling of Ca\(^{2+}\) into the ER by residual SERCA activity. This would also account for the transient increase in [Ca\(^{2+}\)] at the 20 s time point (Fig. 3A).

Translocation of STIM1 by Low and High Concentrations of Thapsigargin—STIM1 has been proposed to be an essential regulatory protein for SOCE (10–13). It is translocated to the plasma membrane region of cells upon depletion of internal Ca\(^{2+}\) stores, and this translocation has been associated with activation of SOCE. We have used TIRFM to examine localization of heterologously expressed YFP-STIM1 in HSG cells.
Regulation of SOCE

Both low and high concentrations of Tg stimulated movement of YFP-STIM1 in the subplasma membrane in cells maintained in a Ca\(^{2+}\)-containing medium in contrast to control cells expressing mYFP alone, which does not change (Fig. 4A). However, although there was a fast and almost uniform increase in STIM1 puncta with 1 \(\mu\)M Tg, puncta were detected at 2 min and maximum by 4 min, translocation of STIM1 with 1 \(\mu\)M Tg addition. The \ast\erisk shows the rate of maximal Ca\(^{2+}\) influx (units/s) induced by 1 \(\mu\)M Tg with 1 \(\mu\)M Ca\(_{12180}^{2+}\) added 300 s after the Tg addition. Data are plotted as mean ± S.E. \((n = 3)\). Mn\(^{2+}\) influx was induced by 1 \(\mu\)M (dotted line) and 1 \(\mu\)M Tg (solid line). Cells were stimulated with Tg in Ca\(^{2+}\)-free medium, and 100 \(\mu\)M MnCl\(_2\), was added 50 (F), 150 (G), and 250 s (H) after the addition of Tg. Relative fluorescence at 365 nm is shown (these traces represent average fluorescence changes from more than 70 cells. Similar results were obtained in four separate experiments).

Depletion of Peripheral Ca\(^{2+}\) Stores Is Associated with STIM1 Relocation and SOCE Activation—
We assessed the localization of the ER stores involved in STIM1 regulation of SOCE by using several different experimental protocols. First, BD-Tg and live cell confocal imaging were used to determine the extent of diffusion (and thus localization) of Tg in HSG cells during activation of SOCE. 1 \(\mu\)M BD-Tg rapidly induced strong labeling of all of the ER (Fig. 5B, top, shows x–y image). The x–z image (Fig. 5B, bottom) demonstrates that this labeling is predominantly perinuclear. In comparison, the pattern of labeling seen with 1 \(\mu\)M BD-Tg was quite distinct. Strong punctate labeling was seen only in the subplasma membrane region (Fig. 5A, top, shows x–y image) with very little intracellular fluorescence. This was confirmed by the x–z image of the cells (Fig. 5A, bottom), which clearly shows the peripheral localization of this signal. Overlay of Bodipy-fluorescein and differential interference contrast images of selected cells are shown in Fig. 5C. Further, specificity of labeling was assessed by preincubation of cells with 2 \(\mu\)M Tg for 3 min before treatment with 1 \(\mu\)M BD-Tg. This preincubation dampened the labeling of the cells with BD-Tg (Fig. 5D); at higher [BD-Tg], initial fluorescence was similarly dampened by preincubation of cells with an equivalent concentration of nonfluorescent Tg. Fluorescence was measured in selected regions of the cell following stimulation with 1 \(\mu\)M Tg (Fig. 5E) (images were collected up to 3 min, and data from the first 150 s are shown; note that SOCE was maximally activated by 1 \(\mu\)M Tg within 150 s). BD-Tg fluorescence in the subplasma membrane region increased within the 5 s after Tg addition and continued to rise, leveling off at about 1000 s. Signal in the nucleus did not significantly increase until about 1000 s. Fluorescence in the internal region was less than in the subplasma membrane ER and displayed a slow, somewhat linear increase after a longer initial lag. Thus, with 1 \(\mu\)M BD-Tg, initial labeling was mostly limited to the subplasma membrane region of the cell, suggesting that SOCE activation by 1 \(\mu\)M Tg is coincident with the presence of Tg in the subplasma membrane region of the cell. With time, there was further diffusion of Tg into the more internal region of the cell and more global inactivation of SERCA in the cells but without a corresponding increase in SOCE. The peripherally located 1 \(\mu\)M BD-Tg during activation of Ca\(^{2+}\) entry suggests that the ER in this region is depleted rather than the more internal ER. This was examined using a mathematical model based on the data in Fig. 5 and in a
previous report (15). We wanted to test whether a model with two ER compartments that are functionally distinct but slowly equilibrate with each other through diffusion of Ca\(^{2+}\) between them (see supplemental materials for details) could account for the data in Fig. 3, A–C. Supplemental Fig. 1, A–C, confirms that this simple model reproduces those observations. The simulations further predict (supplemental Fig. 1, D–F) that when cells are treated with 1 nM Tg, there is greater depletion of the local subplasma membrane Ca\(^{2+}\)-store than the internal ER within the time frame for activation of Ca\(^{2+}\) entry. Thus, the simulations agree well with our hypothesis that activation of Ca\(^{2+}\) entry is associated with the depletion of peripheral ER Ca\(^{2+}\) stores.

This was directly confirmed by measuring the depletion of Ca\(^{2+}\) stores in the subplasma membrane region of the cells ([Ca\(^{2+}\)]\(_{\text{sub}}\)) by using Mag-Fluo4 and confocal microscopy. Images of the whole cell were taken, and changes in the fluorescence of selected regions of interest in the cell were determined. 1 nM or 1 μM Tg induced a faster decrease of the fluorescence in the subplasma membrane region ER (ER\(_{\text{sub}}\)) than in the internal ER (Fig. 6, A and B; Fig. 6C shows fluorescence in unstimulated cells). Furthermore, the decrease with 1 μM Tg in both ER regions was faster than with 1 nM Tg. It should be noted that the decrease in Mag-Fluo4 fluorescence (representing ER [Ca\(^{2+}\)]) is relatively slower than the increase in Fura-2 fluorescence (representing [Ca\(^{2+}\)]\(_{\text{nuc}}\)) under the same conditions. This difference is most likely due to the higher [Ca\(^{2+}\)] in ER compared with the cytosol. Thus, the relative changes in fluorescence are larger in the cytosol than in the ER. A similar slow decrease in ER [Ca\(^{2+}\)] but faster increase in [Ca\(^{2+}\)] have been reported previously in cells treated with Tg or other SERCA inhibitors (30–32). In aggregate, SOCE appears to be fully activated at <50% depletion of the ER\(_{\text{sub}}\) (at this time point, there is a <15% decrease in [Ca\(^{2+}\)] of the internal ER). These data agree well with the predictions made by the model.

ER stress response is a hallmark of global depletion of ER Ca\(^{2+}\) and has been reported to occur in cells treated with relatively high concentrations of Tg and agonists, within the range used to activate SOCE (33, 34). One of the earliest events in the unfolded protein response to ER stress is activation of the kinase PERK, which leads to inhibition of protein synthesis. Fig. 6D shows that PERK is activated within 3 min after stimulation with either 100 μM CCh or 1 μM Tg, detected as phosphorylated PERK. More significantly, treatment of cells with 1 μM Tg significantly increased cell death within 5 min (Fig. 6E; the effect of CCh on cell viability was not examined). However, low concentrations of Tg (1 and 10 nM) did not induce activation of PERK (Fig. 6D) or cell death for up to 15 min (Fig. 6E). Consistent with these findings, 1 μM Tg induced global redistribution of STIM1 into punctae following stimulation when compared with con-
Regulation of SOCE

![Graphs and images related to the text content]

that ER is present in close proximity to the plasma membrane. These data agree well with recent studies reported by Lewis and co-workers (7, 8). Importantly, both 1 nM and 1 μM Tg induced sustained [Ca^{2+}] increases in this region (Figs. 7, B and C; relative changes in Fluo-4 fluorescence measured using TIRFM are shown) in cells maintained in a normal Ca^{2+}-containing external medium. Fluorescence increase was greater and faster with the higher [Tg]. When 1 μM Gd^{3+} was included in the external solution to block SOCE, the increase was smaller and more transient in both cases (Fig. 7, D and E), suggesting that both Ca^{2+} release and Ca^{2+} entry contributed to the [Ca^{2+}], increases seen in Fig. 7, B and C. However, internal Ca^{2+} release in the subplasma membrane region appears to be less when cells are treated with low Tg, since the change in Fluo-4 fluorescence induced by 1 μM Tg was faster and larger (Fig. 7D) that that seen with 1 nM Tg (Fig. 7E). A Ca^{2+} add-back protocol was used to measure SOCE (Fig. 7, F and G). The relative fluorescence changes induced by 1 nM and 1 μM Tg induced in a Ca^{2+}-free medium were similar to those seen in cells stimulated in the presence of 1 μM Gd^{3+} (note the difference in scale for traces compared with those used for Fig. 7, B–E). Importantly, the readdition of Ca^{2+} induced comparable increases in Fluo-4 fluorescence in cells treated with 1 μM and 1 nM Tg (Fig. 7, F and G), suggesting that similar SOCE was induced under these two conditions.

Mag-Fluo4 and TIRFM were used to confirm the depletion of peripheral Ca^{2+} stores by low and high [Tg]. As shown in Fig. 7H, both 1 nM and 1 μM Tg induced a similar decrease (about 50–60%) in Mag-Fluo4 fluorescence in the subplasma membrane regions in cells. Thus, peripheral ER depletion under these two conditions is similar. The apparently higher [Ca^{2+}], increase in this region in 1 μM Tg-treated cells (Fig. 7, B–E) can be attributed to rapid diffusion of Ca^{2+} released more internally in the cells to the periphery (35).

DISCUSSION

The data presented above demonstrate that the peripheral relocation of STIM1 and activation of SOCE are determined by the status of Ca^{2+} in ER localized in the subplasma membrane rather than in more internal regions of the cell. A key finding of this study is that low [Tg] (1 nM) activates SOCE to the same extent as high [Tg] (1 μM) but with much less internal Ca^{2+} store depletion. Importantly, the SOCE regulatory pro-
Regulation of SOCE

FIGURE 7. Tg-stimulated [Ca\(^{2+}\)] changes in the subplasma membrane region. A, localization of the ER network within the subplasma membrane region using the ER-Tracker Red dye; the left shows an epifluorescence image, and the right shows a TIRF image. TIRFM was used to monitor [Ca\(^{2+}\)], with Fluo-4 (B–G) and (Ca\(^{2+}\)] in the ER with Mag-Fluo4 (H) fluorescence in the subplasma membrane region of HSG cells (details under “Experimental Procedures”). Each analog plot showing Ca\(^{2+}\) release and Ca\(^{2+}\) entry is representative of at least two experiments, with each trace showing the average for at least 20 cells. B–E, cells were stimulated with Tg in Ca\(^{2+}\)-containing medium, with or without 1 mM GdCl\(_3\) (Gd\(^{3+}\)). Basal Ca\(^{2+}\) influx is as shown in B. F and G, cells were initially stimulated with thapsigargin (Tg) in Ca\(^{2+}\)-free medium, followed by the readdition of 1 mM CaCl\(_2\) (fluorescence increase in each case was similar in the presence of Gd\(^{3+}\) or in Ca\(^{2+}\)-free medium; note that the scales in F and G are different from those in B–E). Basal Ca\(^{2+}\) influx is shown in F. H, cells were stimulated with Tg in Ca\(^{2+}\)-free medium. Images at 0 and 4 min after the Tg addition are as shown. For control cells, buffer was added instead of Tg.

tein STIM1 is relocalized primarily in the peripheral region of cells stimulated with 1 mM Tg in contrast to the more global relocation seen at the higher [Tg]. By using 1 mM BD-Tg to examine the extent of diffusion of Tg during activation of SOCE, we show that 1 mM Tg diffuses into the subplasma membrane region of the cells during the time required to maximally activate SOCE and relocalize STIM1 in this region. The presence of Tg in this region was temporally correlated with greater depletion of Ca\(^{2+}\) in ER localized in the periphery of the cells rather than in more internal regions. Finally, we show that under conditions where there is recycling of Ca\(^{2+}\) and incom-
Regulation of SOCE

of store depletion and therefore the time required for activation of SOCE as well as its magnitude is determined by recycling of Ca\(^{2+}\) into the ER, either from the cytosol or from the external medium via Ca\(^{2+}\) entry. When Ca\(^{2+}\) was used as the charge carrier, the lag for onset of the current was relatively longer with 1 nM Tg than with 1 \(\mu\)M Tg, and the magnitude of the current was also lower. However, when Na\(^+\) was used as the charge carrier, (i) the magnitude of the current was similar in the two conditions, and (ii) although the lag with the lower [Tg] was reduced, it was still larger than that seen with 1 \(\mu\)M Tg. Similarly, Mn\(^{2+}\) entry was initially (<150 s) lower with 1 nM Tg. Further, we observed that \(I_{\text{SOCE}}\) activated by low [Tg] was also relatively more stable than when stimulated by high [Tg]. These findings can be explained by the Ca\(^{2+}\) recycling that occurs at the lower [Tg] due to residual SERCA activity. Not only does this result in incomplete or delayed ER Ca\(^{2+}\) depletion, but it also lowers ambient [Ca\(^{2+}\)] in the vicinity of the Ca\(^{2+}\) entry channel, thus attenuating Ca\(^{2+}\)-dependent feedback inhibition of the channel (1, 3, 19). An important finding that demonstrates the relevance of the peripheral ER store status is that at the lower [Tg], STIM1 relocation is more prominent in cells stimulated in medium without external Ca\(^{2+}\). We suggest that under these conditions, Ca\(^{2+}\) in the peripheral stores is sufficiently depleted (i.e., concentration is below that required for optimal binding to STIM1) to cause STIM1 relocalization and SOCE activation.

Based on our findings, we propose that activation of SOCE is determined by the [Ca\(^{2+}\)] in subplasma membrane ER. SOCE is activated by depletion of ER in this region and is not further increased by additional depletion of more internal ER. Our data also provide a possible explanation for activation of SOCE by agonist-dependent store depletion. Typically, low [agonist] induces [Ca\(^{2+}\)], oscillations, which in some cases do not appear to be associated with SOCE (41), whereas higher [agonist] or [IP\(_3\)] induces substantial ER depletion and maximally activates SOCE. We have shown here that low and high [CCh] induce similar relocation of STIM1 in the periphery of the cells, but only high [CCh] induces global relocation of STIM1. This indicates that low [CCh] probably induces depletion of peripheral but not internal ER. As suggested by our observations with Tg, small depletions of Ca\(^{2+}\) in the peripheral or internal ER might not lead to detectable SOCE due to rapid recycling of Ca\(^{2+}\). However, higher [IP\(_3\)] can induce substantial global Ca\(^{2+}\) depletion, resulting in SOCE that is easily detected. Consistent with this suggestion, Won and Yule (35) have demonstrated that Ca\(^{2+}\) entry induced by low concentrations of carbachol is not detectable using wide field microscopy but can be readily detected using TIRFM. In aggregate, our findings agree well with the mechanism proposed by Berridge (5) to describe how the Ca\(^{2+}\) status of peripheral and internal ER regulates SOCE, according to which depletion of peripheral ER or sufficient release of Ca\(^{2+}\) in the internal ER (enough to drain Ca\(^{2+}\) from the peripheral ER) can result in activation of SOCE. Further, the characteristic slow inactivation of SOCE that occurs as internal stores are refilled (6, 29, 42) can also be explained. Ca\(^{2+}\)-entering the cell via SOCE is taken up into subplasma membrane ER, from where it diffuses into the internal ER if the latter is depleted. As the internal ER is refilled, [Ca\(^{2+}\)] in the subplasma membrane ER will increase, resulting in inactivation of SOCE by an as yet unidentified mechanism. Whether this is correlated with STIM1 disassociation is not yet known. As long as the internal ER stores are depleted, SOCE will remain activated. Thus, SOCE ensures refilling of internal Ca\(^{2+}\) stores, irrespective of the route of depletion, and protects against generation of ER stress and cell death.

In conclusion, STIM1, has been suggested to be an essential regulatory component of SOCE (7, 10–13). Studies reported recently have shown that stimulation of cells induces STIM1 to aggregate into punctae in the subplasma membrane region of the cells (7, 8, 10, 13), which appear to be causal in activation of SOCE. It is further suggested that these punctae indicate the localization of the functional unit of SOCE. The present data demonstrate that mobilization of STIM1 and activation of SOCE are associated with the decrease of Ca\(^{2+}\) in ER, which is localized within the subplasma region of the cell. Thus activation of SOCE by STIM1 is determined by the [Ca\(^{2+}\)] in the peripheral Ca\(^{2+}\) store where STIM1 is also localized. As long as [Ca\(^{2+}\)] in this store is below the threshold for binding to the STIM1 EF-hand domain, STIM1 will be localized in punctae, and SOCE will remain activated. Further studies are required to determine the exact molecular interactions involved in the generation of STIM1-containing punctae and how exactly these punctae regulate gating of the SOCE channel.

Acknowledgments—We are grateful to Dr. Tobias Meyer (Department of Molecular Pharmacology, Stanford University) for kindly providing the YFP-STIM1 DNA. We are also grateful to Dr. Vincent Schram (NICHD, National Institutes of Health) for assistance in TIRF, which was performed at the Microscopy and Imaging Core (NICHD, National Institutes of Health).
